

Double circulation

Mammals have a more efficient circulation than fishes. Blood pumped by a fish's heart moves through the gills to pick up oxygen, travels around the rest of the body, and only then returns back to the heart. However, in mammals, blood returns to the heart directly after the lungs. It then has more pressure when it flows to the cells, making exchanges easier. This is why mammals have four chambers in their hearts—both an upper and lower chamber for each circuit.
